Biostatistics in Research Practice

Exercise: Folate supplementation

This exercise is a general paper critique taking in several aspects of statistics, but including time to event data analysis.

Read the attached paper ‘Taking folate in pregnancy and risk of maternal breast cancer’ (Charles D, Ness AR, Campbell D, Davey Smith G, Hall MH. (2004) *British Medical Journal* 329, 1375-1376.) On publication this got a lot of coverage in newspapers and on radio and TV news, warning women of the risk of cancer, and in particular breast cancer, involved in taking folate. Read the paper and answer the following questions.

a) This trial is described as ‘randomised’ (Comment). Was it and to what problems might the method of allocation used lead?

b) The trial is described as ‘double blind’? What features of the design suggest that this is not true?

c) What other feature of the reported trial design suggests that we are not being given a full account of this trial?

d) For 5 mg folate and all mortality, the hazard ratio was 1.20 (Table). What is a hazard ratio, and what does 1.20 tell us? Why was this method used?

e) For 5 mg folate and all mortality, the 95% confidence interval for the hazard ratio was 0.84 to 1.71 (Table). What is a confidence interval and what does ‘0.84 to 1.71’ tell us?

f) For 5 mg folate and all mortality, the P value for the hazard ratio was 0.33 (Table). What is a P value and what does ‘0.33’ tell us?

g) For 5 mg folate and all mortality, why is the hazard ratio, 1.20, not in the middle of its confidence interval, 0.84 to 1.71? As the confidence interval does not include zero, is it possible for the difference between folate and placebo to be not significant?

h) What is meant by ‘adjusted hazard ratio’ (Table)? What method was used to adjust it?

i) What assumptions about the data must we make for the adjustment analysis? Which one is clearly violated here?

k) What feature of the significance tests in this trial should make us wary? What could we do about this?

l) How good is the evidence from this paper that taking folates increases the risk of breast cancer?
Taking folate in pregnancy and risk of maternal breast cancer

Deborah Charles, Andy R Ness, Doris Campbell, George Davey Smith, Marion H Hall

Taking folate before conception and then for the first three months of pregnancy reduces the risk of recurrence of neural tube defects, and fortification of food has been proposed. The effects of long term exposure to high concentrations of supplemental folate are unknown, and antimitabolite effects are theoretically possible. Data on the long term effects of increased folate intake in pregnancy are limited. We followed up a large trial of folate supplementation in pregnancy from the 1960s. We examined the association between folate status and death, and we also analysed the effects of folate supplementation.

Participants, methods, and results

From June 1966 to June 1967, 3187 women were identified as potentially eligible for a trial of folate supplementation. At her booking visit, the mother's age, gestation, parity, weight, and blood pressure were recorded, and blood was taken to measure serum folate concentrations. Tablets were supplied in six colours, two of which contained folate in 0.2 mg and 5 mg daily doses. The tablets were kept in numbered drawers and distributed in sequence. The trial was double blind. The husband or partner's occupation at the time of delivery was used to determine social class. Linking the trial data to the Aberdeen maternity and neonatal databank added information on maternal smoking and maternal height. No women withdrew from the trial. Compliance was assessed by self report and by measurement of folate status.

The records were linked with those held by the National Health Service Central Registry in Edinburgh and the cause of death ascertained. In all, 3037 women were recruited to the study, and 2928 were randomised. In the placebo group, 1.9% reported that they had not taken their tablets regularly compared with 1.7% in the group taking 0.2 mg folate and 3.2% in the group taking 5 mg. Initial folate concentrations were similar in the three groups. For later folate measurements there was a dose-response relation between dose of folate and folate status. Baseline characteristics of the women in the three treatment groups were comparable.

By the end of September 2002, 210 women had died; 40 deaths were attributable to cardiovascular disease, 112 to cancer, and 31 to breast cancer (table). Unadjusted and fully adjusted hazard ratios for mortality from all causes, deaths attributed to cardiovascular disease, cancer, and breast cancer in the groups given folate supplements in the Aberdeen Folate Supplementation Trial, 1966-7 (n=2928)

Comment

In women randomised to high doses of supplemental folate, all cause mortality was about a fifth greater, and the effects of long term exposure to high concentrations of supplemental folate are unknown, and antimitabolite effects are theoretically possible. Data on the long term effects of increased folate intake in pregnancy are limited. We followed up a large trial of folate supplementation in pregnancy from the 1960s. We examined the association between folate status and death, and we also analysed the effects of folate supplementation.

The records were linked with those held by the National Health Service Central Registry in Edinburgh and the cause of death ascertained. In all, 3037 women were recruited to the study, and 2928 were randomised. In the placebo group, 1.9% reported that they had not taken their tablets regularly compared with 1.7% in the group taking 0.2 mg folate and 3.2% in the group taking 5 mg. Initial folate concentrations were similar in the three groups. For later folate measurements there was a dose-response relation between dose of folate and folate status. Baseline characteristics of the women in the three treatment groups were comparable.

By the end of September 2002, 210 women had died; 40 deaths were attributable to cardiovascular disease, 112 to cancer, and 31 to breast cancer (table).
What this paper suggests

Women taking high doses of folate throughout pregnancy may be more likely to die from breast cancer in later life than women taking no folate.

What research is needed now

This may be a chance finding, so further studies should examine the association between folate supplementation in pregnancy and risk of breast cancer.

Commentary: Folic acid fortification remains an urgent health priority

Godfrey P Oakley, Jack S Mandel

Charles and colleagues report a non-statistically significant association between short term prenatal consumption of folic acid and breast cancer. As the authors note, even though these data are from a randomised controlled trial, they had no prespecified hypothesis. The randomised controlled trial sought to evaluate the effect of antenatal folate consumption and pregnancy outcomes, not breast cancer. Only 31 breast cancer deaths were found, and the confidence intervals were wide and include one. We believe that the most likely explanation for the reported association is chance.

In contrast to the results reported by Charles and colleagues, the existing literature indicates that increased chronic consumption of folate and higher blood folate concentrations lower the risk of breast cancer, especially among women who consume one or more drinks of alcohol a day. Shrubsole and colleagues found, in a population based study of 1321 cases and 1382 controls, that dietary folate is inversely associated with breast cancer (odds ratio 0.71; 95% confidence interval 0.56 to 0.92). In a prospective follow up cohort, Zhang and colleagues did a nested case-control study, which included 712 breast cancer cases and 712 controls. Comparing women in the upper quintile for blood folate with those in the lowest quintile, they reported a protective relative risk of 0.73 (95% confidence interval 0.58 to 0.92). This is consistent with the findings of a number of case-control studies, including a large randomised controlled trial. Thus, there are biologically plausible mechanisms by which increasing folic acid consumption would lower the risk for breast cancer.

Our argument that Charles’ and colleagues’ findings is a chance one is buttressed by these epidemiological and mutation studies, which indicate that more folic acid is likely to prevent breast cancer rather than to cause it. Charles’ report should not deter mandatory folic acid fortification of wheat and corn flour around the world. Mandatory fortification should be immediately implemented for the known benefits of preventing birth defects and anemia. Folic acid fortification in the United States was followed by a 23% reduction in neural tube defects and improved iron status. The benefits for public health improvement from fortification include lower rates of maternal periconceptional folate deficiency as well as lower rates of folate deficiency among the poor. Folic acid fortification continues to be bad policy.

Competing interests: GPO is coinvestigator (while at CDC, compensation will be under the regulations of CDC) of a patent that covers adding folic acid to contraceptive pills and JSM is a paid consultant to Ortho McNeil on this issue.
